Abstract

The limited nature of data on employment referrals in large business and household surveys has so far impeded our efforts to understand the relationships among employment referrals, match quality, wage trajectories, and turnover. Using a new firm-level data set that includes explicit information on whether a worker at the company was referred by a current employee, we are able to provide rich detail on these empirical relationships for a single U.S. corporation and to test various predictions of theoretical models of labor market referrals. Our results align with the following predictions: 1) referred candidates are more likely to be hired, 2) referred workers experience an initial wage advantage, 3) the wage advantage dissipates over time, 4) referred workers have longer tenure in the firm, and 5) the variances of the referred and nonreferred wage distributions converge over time. The richness of the data allows us to analyze the role of referrer-referee relationships, and the size and diversity of the corporation permit analysis of referrals at a wide variety of skill and experience levels.

Key words: referrals, networks, personnel, wage mobility, turnover

---

The views expressed in this paper are those of the authors and do not necessarily reflect the position of the Federal Reserve Bank of New York or the Federal Reserve System.

1 Introduction

There is an empirical consensus, both in economics and in sociology, on the widespread use of informal referrals in the labor market.[1] For instance, Corcoran et al. (1980) analyze national data from the Panel Study of Income Dynamics (PSID) and find that between 52% and 58% of male workers under the age of 45 heard about their current job from friends or relatives; for their first job these estimates range between 55% and 67%.[2] However, the information on referrals is often indirect, and there is little direct evidence on the impact of labor market referrals on the quality of the matches between firms and workers.[3]

We present new evidence on the empirical relationships among employment referrals and outcomes for workers based on a novel panel dataset on a single U.S. corporation, in which we observe both explicit referral status and a detailed picture of the hiring process and employment spell. We use these uniquely rich data to test the predictions of the long-established theoretical literature on labor market referrals, and to provide new descriptive evidence on the role of referrals at different skill levels and by provider-recipient relationship.

We find that referred candidates are more likely to be hired, and hired referred workers experience an initial wage advantage, all else equal, relative to non-referred workers. The initial referred wage advantage shrinks over time and dissipates by the third year of employment; starting with the fifth year the referral-wage relationship is reversed. Referred workers experience substantially less turnover, and their salary variance converges to that of non-referred workers over time. Each of these findings is consistent with the predictions of established labor market referral models, particularly those that view the distinction between referred and non-referred workers from the perspective of Jovanovic-style learning about match productivity. On the other hand, we find on average no differences in promotion rates between referred and non-referred workers: insofar as promotions reflect productivity, this finding is at odds with the theoretical literature, which tends to predict higher match productivity for referred workers.

[1] See Ioannides and Datcher Loury (2004) and Topa (2011) for surveys of the economics literature, and Marsden and Gorman (2001) for a survey of the sociology literature.

[2] See also Datcher (1983). Pellizzari (2004) analyzes a large panel dataset of European households (the European Community Household Panel) and finds that between 25% and 40% of respondents in most countries heard about their current job through informal contacts. On the employer side, Marsden (2001) and Holzer (1987b) use national surveys of U.S. firms and find that a little over one third of firms surveyed in 1991 and in 1982 (respectively) often used referrals from current employees when publicizing vacancies.

[3] A notable exception is Datcher (1983), which we discuss below.

Further, the wide range of skill and experience levels represented in this corporation permit detailed analysis of the role of referrals for workers from support staff to company executives. Overall, referrals appear to play substantially different roles in the hiring of support staff and executives. Their relationship with the probability of a job offer follows something of a U-shape, with sizable, significant positive associations between referral and offer probability for both lower skilled and executive positions. Most rank-and-file workers experience substantial referral salary advantages, with the largest estimated advantage going to support staff. The association between referral and tenure in the firm is large and positive for support staff, and it decreases more or less monotonically with staff level.

Our dataset also enables us to match referral providers and recipients within the firm, and therefore to construct measures of affinity between referrers and referred along various dimensions. Our analysis of the different types of referral matches yields some additional insights. First, we find that most referrals take place between a provider and a recipient with similar characteristics in terms of age, gender, ethnicity, education, as well as division and staff level within the corporation. This is consistent, on the one hand, with the well-documented extent of assortative matching in social networks, and on the other hand with the idea that referrals tend to be used by firms when they can provide a better signal about the referred worker's match productivity (assuming that higher affinity is associated with more informative signals). Second, we find some indication that referred workers may be more productive that non-referred, for some types of referral match: referrals from a higher to a lower staff level are associated with faster promotions; further, the salary trajectory of referred workers stays persistently higher than that of non-referred when referral providers are in a higher staff level, have relatively low tenure, or work in a different division. The tenure and division findings in particular are difficult to reconcile with a "favoritism" or "influence" interpretation of referrals.

It is important to note here that this paper does not attempt to make any causal claims about the impact of job referrals on outcomes. We do not have, in our data, any exogenous source of variation in job candidates' or hired employees' referral status, nor do we observe a rich enough set of demographic or labor market characteristics to hope to control for selection into different job search methods. Our goal in this paper is to test the equilibrium predictions of leading models of labor market referrals, as well as to enrich economists' descriptive understanding of the behavior of

referrals by provider-recipient relationship and across skill levels. Our results, by and large, support the predictions of learning-based models of labor market referrals.

The plan of the paper is as follows. Section 2 relates this paper to the rich and varied empirical literature on employee networks in general and referrals in particular. In Section 3 we review existing theory on labor market referrals and note several testable predictions. Section 4 describes our new firm-level data on job candidates and employee referral status, tenure outcomes, and promotion and salary trajectories. The empirical specifications used to test the various predictions generated by models of employee referrals, results of these tests and other empirical findings are found in Section 5. Section 6 concludes.

2 Related empirical literature

Empirical research on labor market referrals has emphasized the identification of effective proxies for referred worker status, as a result of the difficulty of measuring referral status in most relevant data sources. Recent research focuses on whether neighbors cluster in the same firm or area as an indication of the strength of informal referral networks (Bayer et al. 2008 and Hellerstein et al. 2008). Others study family based networks (Kramarz and Nordstrom Skans 2007) and educational institutions (Oyer and Schaefer 2009). Giuliano et al. (2009) and Aslund et al. (2009) find a relation between the ethnic status of managers and the ethnic composition of new hires using data from one large U.S. retail firm and Swedish social security data, respectively. Dustman, Glitz, and Schoenberg (2011) use ethnic minority groups as a source of variation in network distance between current employees and new hires in German employment data. Heath (2011) uses direct data on referrer-referred pairs from the Bangladeshi garment industry to test the predictions of a model in which referrals alleviate a moral hazard problem (the employer makes the referrer responsible for the referred worker's effort).

With regard to the impact of referrals on hiring probabilities, Holzer (1987a) finds that the probability of obtaining a job or receiving an offer through personal contacts is higher than that through formal methods. Holzer (1988) also finds that among all search methods, informal methods (personal contacts and direct applications) generate the most offers and acceptances conditional on offer. The high fraction of jobs found through informal means reflects both high usage and high

productivity of these methods. With regard to match outcomes, Datcher (1983) uses PSID data and finds lower turnover (quit rates) in jobs found through personal contacts rather than formal means, for black and college educated workers but not for those with high school educations or less.

Three revealing studies of referral based on firm-level data and explicit referral information address the subject from a sociological perspective. Fernandez and Weinberg (1997), Fernandez and Castilla (2000, 2001) and Castilla (2005) use data from a retail bank and a call center to study the role of referral networks in hiring for low to moderate skill jobs. Much of the focus of these papers is on the hiring stage, and on initial productivity. Major findings include that referred applicants are more likely to be hired after controlling for other observables, that referrers do have relevant information about referred employees and that there is some evidence of assortative matching between referrer and referred. Castilla has direct measures of worker productivity from a call center and finds that referred workers are in fact more productive.

However, these studies do not follow employees for long post-hire periods, and they generally do not rely on the tools of labor economics. Our study is the first, to our knowledge, to use explicit data on individual employees' referral status to relate referrals to both immediate and long-term employment outcomes including starting salary, salary trajectory over time, promotion patterns and stability of the job match, and hence we are the first, again to our knowledge, to be able to test the collection of predictions generated by the theoretical literature on employee referrals regarding salary trajectories, promotion and turnover using explicit data on employees' referral status. In addition, we observe various measures of affinity between referrer and referred along several dimensions, so we can study whether and how these referral effects vary depending on the nature of the match between referral provider and receiver.

3 Theoretical models of employment referrals and their predictions

Simon and Warner (1992) and Montgomery (1991) are two seminal papers in the theory of labor market referral. Simon and Warner embed employee referrals in a Jovanovic (1979, 1984) model of job matching and turnover, and use this partial equilibrium framework to derive predictions for differences in salary and match duration between referred and non-referred workers. As a result

of their partial equilibrium, dynamic framework, testing the types of predictions generated by the Simon and Warner model involves immediate and ongoing observation of referred and non-referred workers in a single employment spell, a task for which our panel of firm-level data is particularly well suited.[4] Montgomery argues that referrals from current employees may reduce the adverse selection problem an employer faces when trying to hire someone, if there is uncertainty about worker or match quality. The predictions of his model emphasize network density and matching characteristics, along with characteristics of the aggregate wage distribution, and so may be better addressed in broad survey data.

3.1 Prediction 1: Referred applicants are more likely to be hired

More recent theoretical papers on employee referrals include Galenianos (2011) and Dustmann et al. (2011). Galenianos models worker and firm search with and without productivity heterogeneity in the presence of networks that yield (informative) referrals. As the (exogenous) rate at which referrals are generated increases, the aggregate job finding rate rises and labor market tightness decreases. Importantly, the Galenianos model with worker heterogeneity delivers the theoretical implication that workers who meet a firm through referrals are more likely to be hired than workers who meet the firm through random matching. This is because high productivity workers are more likely to be employed and therefore are more likely to refer one of their social contacts. Because of assortative matching, those who are referred are more likely to be other high productivity workers. Therefore, when a worker and a firm meet, a referred job candidate is more likely to be hired than a non-referred one, all else equal. We will be able to test this hypothesis directly with our data. Other predictions include that referrals are associated with the hiring of more productive workers.[5]

[4] Note that Simon and Warner test the predictions of their old boy network model using the 1972 Survey of Natural and Social Scientists and Engineers, a collection of retrospective self-reports on employment experiences. We discuss their findings in conjunction with our own empirical results below. While our data have the advantages of being roughly 30-50 years more recent, being derived from an administrative source and representing a considerably wider range of worker skill levels, their data have the obvious advantage of representing more than one firm.

[5] Note that the Galenianos model emphasizes the roles of the job seeker and potential employer in the context of a matching model, where referrals affect the aggregate job finding rate and the properties of the equilibrium matching function. Therefore, like Montgomery (1991), some of its predictions may be best tested using the business and household survey data on which much of the referral literature has relied to date.

3.2 A simple model of employee referral

We now present a model of job matching that is adapted from the parsimonious model of Simon and Warner (1992) and the enriched specification of Dustmann et al. (2011). Dustmann et al. model both initial worker-firm contact in referral and external markets and the ongoing wage negotiation over time between a matched worker and the firm. In this sense, their approach fits our current purposes particularly well. They generate richer predictions for the employment trajectory than other available models of employee referral, and they have more to say about the wage renegotiation process within a single employment spell. For these reasons, we focus in large part on the Dustmann et al. model and intuitions behind its various predictions.[6] The Dustmann et al. model draws heavily on the specification in Simon and Warner, which in turn is based on the job matching model of Jovanovic. Hence the various approaches on which we pin our tests share common assumptions and intuition.

Consider an economy consisting of N workers and L firms producing according to a constant returns to scale technology, and in which firms may enter (by posting a vacancy) and leave freely. Firms and workers are risk neutral payoff maximizers. When unemployed, workers receive unemployment benefit b. Firms experience cost of an unfilled vacancy k. True underlying productivity y is match-specific and drawn from distribution $N(\mu, \sigma_y^2)$.

When a worker and firm meet, they observe a noisy signal of the match's true productivity, $\widehat{y}_j = y + \varepsilon_j$, where $\varepsilon_j \sim N(0, \sigma_j^2)$ and $j \in \{R, E\}$ indicates the worker's referred or external market status. Given a posting, a referral may or may not be available to the firm according to an exogenous process. The effect of the referral is to modify the informativeness of the productivity signal observed by the worker and firm, so that $\sigma_R^2 < \sigma_E^2$.

Suppose, then, that the (somewhat simplified) timing of events is as follows:

1. A firm chooses to post a vacancy. With positive probability the firm receives an employee referral for the vacancy. Firm and referred worker observe signal $\widehat{y}_R$ of the referred worker's quality.

[6] In the interest of expositional simplicity, we abstract from several features of the problem included in Dustmann et al. Specifically, we assume a zero rate of match destruction and that, as in Simon and Warner, employers and employees observe the true match quality in the second period of employment with certainty, rather than with a positive probability in each subsequent period of employment. Finally, we set aside some structure on the employee network used by Dustmann et al. to allow for equilibrium effects of employment levels on job finding rates and the like. These simplifications allow us to reproduce and discuss certain central intuitions of the Dustmann et al. model briefly in our context. Where more extensive modeling is valuable, we simply refer to the original and discuss its predictions in less specific terms.

The firm makes a wage offer. If the worker turns down the offer, the position remains open and the worker remains unemployed for the duration of the period.

2. Workers who have received no offers and firms that have received no referrals meet in the external market according to a constant returns to scale matching function. On matching, worker and firm receive match quality signal $\widehat{y}_E$. The firm makes a wage offer. If the worker rejects the offer then the vacancy remains open and the worker remains unemployed for the rest of the period.

3. In the next period, each worker-firm pair in an existing match learns the true productivity of the match. The firm makes a new wage offer. If the employee turns down the wage offer then the match is dissolved, the employee becomes unemployed and the position becomes vacant.

3.2.1 Wage and employment determination after true productivity is revealed

Following Jovanovic and Simon and Warner, we impose a zero expected profit condition on the firm, which implies that the expected stream of payments to the worker over the worker's tenure with the firm is equal to the worker's expected value of marginal product. Jovanovic demonstrates that the following pay strategy satisfies this condition: In the first period, the firm offers the worker a wage equal to the worker's expected productivity, conditional on the firm's signal, or $w_j = m_j = E(y|\widehat{y}_j)$.[7] In the second period, the firm offers the worker a wage equal to true productivity y.[8]

Let $J(y)$ represent the value to the worker of remaining employed at known productivity y, and let Q represent the value to the worker of rejecting an offer in favor of unemployed search. The value of unemployed search is stationary and independent of the worker's current productivity match. Therefore, if it is currently optimal for the worker to remain employed at productivity y then it will always be optimal for the worker to remain employed at productivity y. This leads to a reservation productivity y^r, and a value of employment

$$J(y) = \begin{cases} \frac{y}{1-\beta} \text{ where } y \geq y^r \\ \beta Q \text{ where } y < y^r, \end{cases}$$

where β is the worker's discount factor. Hence y^r is determined by $\beta Q = y^r/(1-\beta)$. Note that

[7] Note that $\sigma^2_{m_j} = \left(\frac{1}{\sigma^2_y} + \frac{1}{\sigma^2_j}\right)^{-1}$ is the variance of y conditional on signal $\widehat{y}_j$.

[8] As in Jovanovic and Simon and Warner, the equilibrium pay strategy is not unique.

this reservation value is common to matches produced by referrals and matches produced by the external market.

3.2.2 Wage and employment determination with unknown productivity

Define W_{1j} as the value of initial wage offer m_j from source j for a worker. Given the above,

$$W_{1j}(m_j) = \max\{m_j + \beta E[J(y)], \beta Q\}.$$

Since both m_j and $E[J(y)]$ increase with m_j, while βQ is constant in m_j, there exists a unique reservation wage (or expected productivity), m_j^r, above which the worker accepts an offer from source j, and below which the offer is rejected.

3.2.3 Prediction 2: Referred workers receive higher initial wages

Given the reservation wage property,

$$W_{1j}(m_j^r) = m_j^r + \beta \int J(y) dF(y|m_j^r, \sigma_{m_j}^2) = \beta Q,$$

where $dF(y|m_j^r, \sigma_{m_j}^2)$ is the density of true productivities conditional on current predicted productivity m_j^r. Further, as in Sargent (1987), the initial reservation wage can be related to the ongoing reservation wage according to

$$m_j^r = y^r - \frac{\beta}{1-\beta} \int_{y^r} (y - y^r) dF(y|m_j^r, \sigma_{m_j}^2). \tag{1}$$

Note that the second term on the right hand side of (1) is positive, and hence the initial reservation wage is lower than the ongoing reservation wage. Part of the value to the worker of an initial wage is the possibility that the match productivity will exceed the expected productivity, leading to a higher ongoing wage. The worker is shielded from worse than expected productivity matches by the ability to separate from the firm. The probability mass above the reservation value is increasing in the variability of the conditional productivity distribution. The assumption that $\sigma_R^2 < \sigma_E^2$ implies $\sigma_{m_R}^2 < \sigma_{m_E}^2$, and therefore that the second term in (1) is larger for the external market than for the referred candidate. External market job candidates mark down their reservation wages, relative

to those of referred candidates, in response to the greater up-side potential of their productivity signals. This leads to the result that $m_R^r > m_E^r$; conditional on acceptance, referred workers have higher starting wages than external market workers.

Dustmann et al., Simon and Warner, and Galenianos all predict higher starting wages for referred workers. The intuition driving this result is similar in Dustmann et al. and Simon and Warner, while the source of the difference in Galenianos relies on homophily in referral networks and the higher average productivity of employed than of unemployed workers.

3.3 Prediction 3: The referred worker wage advantage diminishes over time

As noted, Dustmann et al. employ a more complex version of the model than we have described here. As a result, they are only able to generate predictions for the salary trajectory using numerical methods. In an appendix to the paper, on page 34, they report numerical results indicating that the wage advantage accruing to the (still employed) referred worker over the (still employed) non-referred worker diminishes with tenure in the firm.

In a simpler framework, more closely resembling what we have described here, Simon and Warner generate some intuition for this result by considering the limiting cases. Suppose, for example, that referrals perfectly reveal true match productivity in the first period, so that $\sigma_R^2 = 0$. In this case, the referral market reservation match value reverts to $y^r = \beta Q(1-\beta)$, and, as a result, the first and second period reservation productivity values for the referred case are identical. Further, in this case, referral wages are identical in the first and second periods, with no new information on match productivity revealed at the start of the second period. Assuming a less than perfectly informative signal for the external market ($\sigma_E^2 > 0$), this implies a flatter wage profile for referred than for non-referred workers. Further, as we discuss in Section 3.2, the model predicts lower separations for referred than non-referred workers. Relatively more external market workers will separate over time, from the low end of the match quality distribution: thus, those external market workers who stay with the firm will exhibit higher wage growth on average because of the non-random differential attrition.

Note that Simon and Warner also consider the predicted effect of referrals where signals regarding referred and non-referred workers' match productivities are equally informative, but referred workers are on average of better match quality. This model generates an initial wage advantage for

the referred but similar wage growth for referred and non-referred workers, and Simon and Warner interpret findings on the time path of the wage advantage of referred workers as a test of the relative importance of mean productivity differences and productivity signal informativeness in explaining the referral advantage. We will be able to explore this question in detail with our dataset.

3.4 Prediction 4: Turnover is lower for referred workers

The lower turnover prediction in Dustmann et al. is analogous to the higher starting salary prediction in Dustmann et al. As discussed above, they demonstrate that the reservation match productivity in the referral market is higher than the reservation match quality in the external market, $m_R^r > m_E^r$. Given that referred workers are better matched to their firms than non-referred workers, the probability mass below the common match productivity reservation value that applies to all workers after productivity is revealed is greater for external market than for referred workers, and so more workers initially hired through the external market separate from their matches following productivity revelation.

More specifically, the probability that a worker separates once true productivity has been revealed is

$$\int_{-\infty}^{y^r} dF(y|m_j, \sigma_m^2) = \Phi\left(\frac{y^r - m_j}{\sigma_m}\right).$$

Hence the probability of a separation, like the σ_m term itself, is an increasing function of σ_j^2.[9]

[9] Returning to Simon and Warner's limiting cases, suppose again that referrals perfectly reveal true match productivity in the first period, so that $\sigma_R^2 = 0$. As discussed, in this case the referral market reservation match value reverts to $y^r = \beta Q(1-\beta)$, the first and second period reservation productivity values for the referred case are identical, and wages are identical in the first and second periods. No new information on match productivity is revealed at the start of the second period. As a result, no referred worker separates from the firm at the start of the second period. Assuming a less than perfectly informative signal for the external market ($\sigma_E^2 > 0$), this limiting case generates the extreme prediction that all turnover takes place among external market hires, and all referred workers remain employed.

Alternatively, consider the case in which the external market productivity signal is completely uninformative. Then the external market expected productivity distribution collapses to $N(\mu, \sigma_y^2)$ and all external market job candidates meeting firms are hired and draw a wage of μ (presuming a sufficiently favorable underlying match quality distribution for employment to take place). If the referral market productivity signal contains any information, then workers and firms meeting by referral, unlike those meeting in the external market, will be able to reject some lower segment of signalled productivities. Therefore when match quality is fully realized for both external market and referred worker-firm pairs in the second period, the proportion of referred workers with realized match productivities below the common reservation value of $y^r = \beta Q(1-\beta)$ will be smaller than the proportion of external market workers with match productivities below $y^r = \beta Q(1-\beta)$, which will simply equal $\Phi(\frac{\beta Q(1-\beta)-\mu}{\sigma_y})$. Therefore the separation rate for referred workers following productivity revelation will be smaller than the separation rate for non-referred workers following productivity revelation.

3.5 Prediction 5: The referred turnover advantage also diminishes over time

Though our simple two period model, and the simple model of Simon and Warner, cannot address patterns in turnover as tenure in the firm varies more finely, Dustmann et al. model a gradual process of true productivity revelation. This approach allows members of the populations of referred and non-referred workers to be subjected to the common post-revelation reservation match standard gradually over time. As a result, surviving referred and non-referred employees gradually become more similar. Dustmann et al. provide evidence, again numerical, that the difference in the rate of separation from the firm between referred and non-referred workers should diminish over time.

3.6 Prediction 6: Referred workers have higher expected productivity

The higher reservation match productivity of referred workers ($m_R^r > m_E^r$) predicted by the model of Dustmann et al. would seem to predict higher expected match productivity for referred workers in general. Simon and Warner make similar predictions regarding reservation match productivity, and the link to expected match productivity over the full distributions of referred and non-referred workers is more direct in their simpler context. Further, Galenianos generates higher employer predictions of referred worker initial productivity in a decidedly different context. As discussed above, in a lower skilled pool of call center workers, Castilla (2005) finds evidence of higher productivity (in a piece-rate sense) for referred than for non-referred workers. Greater initial or expected productivity of referred workers appears to be a common prediction of the employee referral literature.

3.7 Prediction 7: The variances of referred and non-referred workers' wages converge over time

We also consider the relative variances of referred and non-referred workers' wage distributions. Two forces influence the relative variances. The first is the noisiness of the signal. Let us begin with the expected productivity variances of a referred and an external market candidate, $Var(m_R) = \frac{\sigma_y^4}{\sigma_y^2+\sigma_R^2} > \frac{\sigma_y^4}{\sigma_y^2+\sigma_E^2} = Var(m_E)$. Here we see that the variance of expected productivity decreases with the variance of the signal. A noisier signal leads the firm to place more weight on the population distribution of productivities when determining the initial offer. Since the population distribution is common across candidates, a noisier signal leads the firm to make more similar offers to candidates,

which leads to less varied initial wages.

The second force arises from the difference in referred and external market acceptance thresholds. The distribution of realized initial wages after the offer acceptance decision is a truncation of the normal distribution of expected productivity m_j (which has mean μ and the above variance) at reservation wage m_j^r. The variance of a truncated normal distribution decreases with the truncation point, so, recalling that $m_R^r > m_E^r$, we find that the effect of the reservation wages is to lower the variance of initial wages for referred workers relative to those of external market workers.

On net, the relationship between $Var(w_R)$ and $Var(w_E)$, where w_j represents initial wage, is ambiguous in the context of the theory. One thing that the theory does allow us to say, however, is that the variances will become more similar over time. Once underlying productivity is revealed, and all workers apply ongoing reservation wage $y^r = \beta Q(1-\beta)$, the remaining difference in ongoing wage variances will arise from differences in the initial acceptance thresholds for the two groups. In fact, the closer the initial signal for a group was to being either perfectly informative or perfectly uninformative about true productivity, the closer the ongoing wage distribution will be to a $N(\mu, \sigma_y^2)$ truncated at the ongoing reservation wage of $y^r = \beta Q(1-\beta)$. This change occurs from the first to the second period in the models presented here and in Simon and Warner, and more gradually in the context of the enriched dynamics of Dustmann et al.[10]

Turning to another source on the relative variances of referred and non-referred worker wage distributions, Datcher (1983) posits a simple model of "job shopping", in which "information gathered through knowing someone at the place of employment before hiring lowers the uncertainty about the quality of the match between worker and job." She finds that the variance of the unobserved component of the returns of a job to an individual worker is lower for referred than non-referred workers.

Given the ambiguous prediction regarding the relative variances of the referred and non-referred wage distributions in the above model, and the prediction of lower referred wage variance from Datcher's work, we investigate the relative levels of referred and non-referred wage variances in our data. In addition, we test the model prediction that referred and non-referred wage variances converge over time.

[10] This assumes that μ is an acceptable wage offer in the perfectly uninformative signal case. More detail on the variance convergence prediction has been omitted for length, and is available from the authors.

4 Data and descriptive statistics

This study utilizes a unique dataset that includes all of the hires and applicants of a U.S. corporation which employs between 2,000 and 5,000 workers in the steady state. The corporation hires people for a broad range of tasks with all levels of educational backgrounds and years of work experience. This makes it an ideal sample to study the effect of referrals across a variety of skill and education backgrounds.

4.1 Applicant data

The applicant dataset covers all applicants to the corporation from 2006 to 2010. The data contain information about how the applicant found the position, whether through the corporation's website, campus recruiting, internet job boards, employee referrals, their own initiative, or another source. In our data, an applicant can be associated to an employee referral in one of two ways: either if the applicant indicated the name of a current employee as the source of a referral, or if a current employee "claimed" that candidate as a referral (or both). In either case, once the applicant gets to the interview stage, the information on the referral source is verified by the corporation's human resources department.[11]

We calculate the number of applicants for each position and the portion of the applicants that were referred.[12] We have measures of the staff level associated to each position, which we group into five categories: support, junior, mid-level, senior, or executive staff. The data also include the required years of job experience and education level for the posting, whether applicants received an interview or offer and whether they accepted the offer, and the date of the job posting.

The estimation sample is restricted to include only job postings that result in a hire and those that received more than one applicant. We remove internship postings and positions that were only posted internally in the corporation. When former interns, former employees, or current employees apply for a position, we include them in the calculation of the size of the applicant pool, but

[11] For many positions, if the employee referral leads to a hire and the newly hired worker stays at the organization for longer than six months, the employee who provided the referral receives a small monetary bonus. However, family members, company executives, direct supervisors or recruiters are not eligible for the award. We discuss below other potential sources of bias.

[12] For any given open position at the company, there may be multiple vacancies that the corporation is trying to fill. However, 91 percent of positions are associated with a single vacancy. From here on, we refer to a "position" as a job posting for which there may be a single or several active vacancies.

we remove their individual observations from the estimation sample. If a former intern, former employee, or current employee ultimately is hired for the position, then that job is excluded from the sample. This reflects our impression that these types of applicants likely experience different hiring processes. We also exclude from our data postings for positions for which workers were hired in bulk.

The final sample used in our analysis includes 62,127 job applicants for 315 positions, that resulted in 340 hires. Table 1 summarizes the key statistics of the applicant data. Of all the applicants, 2.9% received interviews and 0.7% got job offers. Almost 50% of the applicants applied to junior staff positions, followed by 27.8% to mid-level staff positions, 18.4% for senior staff jobs, 2.8% for support staff and 1.7% for executive positions. Comparatively, 39.1% of jobs postings were for junior staff positions, followed by 33.7% for mid-level staff, 20.3% for senior staff, 4.8% for support staff, and 2.2% for executives. Similar patterns exist for the education requirements, with about 86% of postings requiring at least a Bachelor's degree. The mean years of experience required is 5.3. On average, 185.2 applicants apply, and 6.7 people interview, for a given posting.

4.2 Employee data

The employee data contain information on all of the hires from 2000 to the first half of 2011. The data detail how the employee applied for the job, whether through internet job boards, the organization's website, college or career fairs, employee referrals, or other methods. As with the applicant data, in order for a worker to be considered an employee referral, either the new hire must have reported the referral when applying for the job, or a current employee must have referred that worker through the company's internal referral system (or both). The referral source is verified by the corporation's human resources department at the interview stage of the hiring process. The employees' rank in the organization, shifts, office locations, full or part-time status, and on-leave status are observed at six month intervals. If the worker leaves the organization or receives a promotion, this information and the timing of the event appear in the data.

We restrict our estimation sample to include only first time hires because of likely differences in the referrals and promotions of former employees and interns compared to other employees. The sample is also restricted to employees in the main location of the company. Interns are excluded from the sample because they are never promoted and they are attached to the corporation for a

brief and externally determined period. Finally, we exclude the top executives in the corporation.

The resulting estimation sample includes 1,774 unique employees, 29% of whom were referred by current employees before being hired. Table 2 provides descriptive statistics for our employee data estimation sample. Annual salary is reported in 2010 dollars and includes base salary, not any performance based pay. The salary figures and the rates reported in the top panel of Table 2 are based on our 12,447 pooled employee semiannual observations. The mean and median annual salaries in the pooled data are similar, at $102,740 and $97,377 2010 dollars respectively. The standard deviation of salaries is substantial, at $45,551, and the salary range, from about $20,000 to over $300,000, is quite broad.

This salary range indicates a wide range of positions held in the corporation. Three percent of observations represent employees who entered as support staff, 36 percent employees who entered as junior staff, 41 percent employees who entered as mid-level staff, 18 percent employees who entered as senior staff and two percent employees who entered at the executive level. The overwhelming majority of employees are full time, day shift workers who are not on leave. However, the sample includes 50 night shift, 99 graveyard shift, 194 on leave and 111 part time employee-observations.

Of the 1,774 unique workers ever observed in our sample, 1,005 (57 percent) are observed to be promoted during the sample window, and 638 (36 percent) are observed leaving the corporation. The mean observed tenure in the organization by 2011 or exit, whichever occurs first, is 3.01 years. The mean time to promotion is 1.66 years. This averages the time between starting at the corporation and first promotions, or between promotions for all occurrences of promotions in the data. For those that receive a promotion, it takes on average 1.62 years to get promoted for the first time. In our sample an average of 151 new employees join the corporation and 56 leave each year. Since our sample contains only employees who began working at the organization in 2000 or later, the actual average number of employees who leave each year is higher. The overall size of the corporation has stayed roughly the same over the sample period.

The dataset also matches people who received referrals at the time of hire with those who provided those referrals.[13] From this, we obtain information about whether or not the provider and receiver of the referral are of the same gender, race, and company division. The data also

[13] Thirty-six out of 509 unique referred employees could not be mapped to their provider's information due to constraints of the available data. (If an employee is referred by someone who moves to another branch of the firm, then that provider's information is removed from the dataset).

include age, staff level, education differences and the provider's tenure at the firm at the time of the referral. For confidentiality reasons, the data only displays whether referral matches are of the same or different gender or race instead of noting individual gender or race. Similarly, we know whether the referrer and referred are within 10 years of the same age, or if the referrer is 10 or more years older, or 10 or more years younger, than the referred. For staff level, we observe whether provider and receiver are at the same staff level, or the provider is at a higher (lower) staff level relative to the referral receiver.

Table 3 describes these variables. The majority of referral matches are between people of the same gender (63.5%), the same race or ethnicity (71.5%), and the same division (73.2%). So, the extent of homophily in referrer-referred pairs along these dimensions is significant. Thirty-six percent of people are referred by people who are at least 10 years older than them. Forty-eight percent of referrals are from providers within 10 years of the receiver's age and 16% are from younger providers. Thus the distribution of providers' ages is slightly skewed towards older providers (relative to receivers).

We also observe whether providers are from a higher or lower staff level than receivers. As discussed above, staff levels consist of support, junior, mid-level, senior, and executive staff. Most referrals are provided by employees in higher (48.1%) and in the same (47.9%) staff levels. Only 4.1% of all employees in our data are referred by employees in lower staff levels. Regarding education level, the data show whether referrer has the same education level as the referred, a higher education level, or a lower education level, marked by their highest attained degree. Forty-nine percent of receivers are referred by providers with the same educational attainment. The rest are referred by providers with more education (17.6%), less (11.2%), or an unknown education level (22.5%). The average referral provider has worked at the firm for 3.1 years at the time the receiver begins working. Tenures for providers range from zero to 11 years.[14]

One meaningful shortcoming of our data in the context of the broad literature on employment is the absence of data on hours of work. Our only measures of hours of work are indicators for whether the employee is working part time and whether the employee is currently on leave. However, there appears to be only modest variation in work hours in this sample. Roughly 97 percent of our sample

[14] Ten individuals in the sample were referred by two people. For these cases, we consider the referrer that is of the same gender, the same ethnicity, the same company division, older, a higher staff level, more educated, and with longer tenure.

of semiannual observations represents full time workers.[15] As a result of our lack of hours data, we are unable to infer hourly wages from annual salaries. We consider annual salary (or log annual salary) as our primary outcome variable for the earnings analysis portion of our empirical work.

In addition, the data do not include either education at the date of first employment or work experience before applying to the organization. In order to estimate the log earnings regressions that are standard in the literature, we require schooling and experience variables. We address this data limitation using the staff category indicators described above. Since we observe the education and experience requirements for each job posting, we have a clear idea of the schooling and experience requirements associated with each staff level. We find that staff categories summarize schooling and experience requirements fairly effectively. Hence we use staff level at entry indicators in our earnings estimation to proxy for the schooling, experience and experience squared regressors employed by the majority of the literature.

A potentially important issue concerns the way in which an employee referral is recorded in our data. As mentioned above, for an applicant (or new hire) to be considered an employee referral in our data it must be the case that either the applicant indicated the referral source when applying for the job, or a current employee referred that person for a position at the corporation through the organization's internal referral system (or both). There are several potential measurement issues here, that may affect our estimation results.

First, there may be under-reporting: someone may be hired through a referral even though the referrer did not bother to fill out the relevant form with the company's referral system, *and*, in addition, the referred worker did not indicate the referral source at the time of the application. The combination of the two events seems unlikely: the referral recipient has the incentive to mention the referral as it likely raises the chances of being offered the job; the referrer, on the other hand, has the incentive to "claim" the referral either for the monetary bonus or for other non-pecuniary benefits. If there is any under-reporting, as long as it is uncorrelated with the referred worker's characteristics, then it will likely only lead to an attenuation bias in our estimates.[16] Second, and perhaps more importantly, it is possible that a current employee's decision to refer someone

[15] Of course, there could be substantial unobserved hours variation among those workers whom the corporation classifies as full time.

[16] However, if the employee's decision to report a referral is correlated with something unobservable about the candidate that in turn affects her likelihood to be hired, then it will be difficult to sign the direction of the bias.

formally may be related to the candidate's success during the various stages of the recruiting and interviewing process for a given posting. This possibility is limited by the details of the referral process: the latest that a current employee can "claim" someone as a referral is at the interview stage, when the recruiter reviews the candidate's initial application. Therefore, the referrer cannot decide ex-post to refer someone, after observing whether the person is actually hired or not.

5 Empirical specification and findings

5.1 Prediction 1: Referred candidates are more likely to be hired

A central prediction of Galenianos (2011), as discussed above, is that referred workers are more likely to be hired, all else equal. Our first empirical step is to test this prediction using our data on the corporation's applicant pool and resulting hires. Note that Castilla (2005), Fernandez and Weinberg (1997), and Fernandez and Castilla (2000, 2001) all confirm this prediction in their bank and call center single-firm hiring studies. Our test of this prediction extends the analysis to a broad range of skill levels and more recent hiring data, and, in addition, informs our findings regarding longer-term worker experiences for this particular corporation.

An initial perspective on the question of whether referrals increase the odds of being hired is provided by the raw interview and job offer rates reported in Table 4. The most common application source in the sample by far is internet job boards: job board applicants constitute 60 percent of the applicant sample. Moving from left to right in the job board row of Table 4, these job board applicants also constitute 40 percent of interviewees, and 24 percent of offer recipients and final hires. In other words, there is a decisive downward trend over the hiring process in the proportion of candidates achieving increasingly serious consideration who are coming from job boards. Similar downward trends over the hiring process can be seen for those who applied through the corporation's website and those who employed via their "own initiative". Referred employees demonstrate the opposite pattern. While only 6 percent of applicants are referred by a current employee of the corporation, 21 percent of interviewees, 27 percent of those receiving offers and 29 percent of those who are hired are referred. The only other applicant sources showing this type of increasing trajectory are the campus recruitment and "other" sources categories.[17] Campus recruitment is a

[17] The "other" category includes a variety of search methods that comprised a small proportion of applicants. These

very small proportion of this organization's hiring efforts, and neither campus recruitment nor other sources demonstrate as steep an increasing trajectory across the hiring process as we observe for referred employees. Though it is necessary to control for observable differences among applicants and positions before making final inferences regarding the relationship between referrals and hiring outcomes, the unmanipulated data in Table 4 indicate a strong association between referral and the odds of an interview or offer.

Next we adopt a more formal approach, modeling the probability of being hired by the corporation in a linear probability framework.[18] Specifically, we estimate

$$H_{ij} = X_i^H \alpha^H + Z_j^H \beta^H + \gamma_t^H t_j^H + \delta^H \chi(t_j > 2007) + \varepsilon_{ij}^H, \tag{2}$$

where X_i^H is a vector of characteristics of applicant i including indicators for applicant source among the set {referral, internet job board, corporate website, own initiative, other source}, Z_j^H is a vector of characteristics of job posting j including number of applicants for the position, proportion of the applicant pool that is referred, the staff level of the position, the experience requirement of the position and the educational requirement of the position, t_j^H is the year the position was posted, $\chi(t_j^H > 2007)$ is an indicator for whether the position was posted since the start of the 2008-09 recession and ε_{ij}^H is an idiosyncratic error associated with the applicant i - posting j pair.

The estimates generated using expression (2) are reported in Table 5. We estimate three versions of the model. In the first, we define outcome H_{ij} as an indicator for whether applicant i was interviewed for position j, and we estimate using the full sample of applicants.[19] In the second, we define outcome H_{ij} as an indicator for whether the applicant was offered position j, and we again estimate using the full sample of applicants. In the third, we condition the estimation sample on applicant i having been interviewed for position j. This leaves us with a sample of 1,811 interviewees. Of these 1,811 interviewees, 428 are offered the position for which they interviewed. We again define H_{ij} as an indicator for whether the applicant received an offer. In this manner we are able to examine not only whether referrals are associated with a greater job offer probability,

methods include staffing agencies, job fairs, print advertising, and professional affiliations.

[18] Our qualitative results are generally robust to a logistic specification, and we include these estimates as Appendix Tables A1 and A2.

[19] We impose the sample requirement that we observe all variables included in the Table 5 estimation for the applicant-position pair.

but also at what stage of the hiring process any estimated referral advantage is manifested.

Our central finding is that referred applicants are indeed more likely to be hired.[20] Among the set of applicant sources, internet job boards produce the largest number of observed applicants, and so we employ job boards as the omitted category. Relative to job board applicants, referred applicants are estimated to be 7.3 percentage points more likely to be interviewed for the position, and 2.4 percentage points more likely to receive an offer. Conditional on having been interviewed, referred applicants are 13.9 percentage points more likely than job board applicants to receive offers.[21] Each of these coefficient estimates for the referred category is significant at the one percent level. Applicants sourced from the corporate website and who applied through their own initiative have interview and offer rates similar to those of job board applicants. As hinted by the Table 4 transition rates, however, "other" applicants, including those produced by campus recruiting, have interview and offer probabilities that are significantly higher than those of job board applicants.[22]

Other regressors in Table 5 pertain to the characteristics of the posting, and therefore their coefficient estimates indicate the characteristics of more and less competitive job postings within the corporation. They are discussed in a brief appendix to the paper.

5.2 Prediction 2: Referred workers receive higher starting salaries

Next we test the prediction that referred workers receive higher starting salaries. First consider the simple linear specification

$$S_{i0} = \alpha^S r_i + X_{i0}^S \beta^S + \gamma_t^S + \varepsilon_{i0}^S,$$

where S_{i0} represents the starting salary of worker i, r_i is an indicator for whether worker i was referred by a current employee of the corporation, X_{i0}^S is a vector of controls measured at job entry including a staff level indicator (as a proxy for schooling and experience at job entry) and indicators for company division, shift, work schedule and leave status, γ_t^S is a calendar year fixed effect and

[20] To be precise, we focus here on two outcomes, being interviewed and receiving an offer. Most people who receive an offer end up accepting it and thus being hired, but we want to abstract here from the candidate's decision on whether or not to accept an offer.

[21] Note that 6.0 percent of job board applicants receive interviews and 32.3 percent of interviewees from internet job boards receive offers.

[22] An interesting side question is whether the corporation views referrals as substitutes or complements to other inputs in the recruiting technology. We find some (weak) evidence of substitution between referrals and other inputs into the screening process: controlling for applicant pool size, the percentage of applicants who get interviews is negatively correlated with the presence of referrals in the pool.

ε_{i0}^S is an idiosyncratic error. Coefficient estimates for the linear starting salary specification are reported in the first column of Table 6, with salary measured in thousands of 2010 dollars. We find that having been referred is associated with a \$1,326 salary premium that is close to being statistically significant at conventional levels (the p-value equals 0.107).

A more conventional specification in the context of the literature is the following log earnings regression:

$$\ln S_{it} = \alpha_0^L r_i + \alpha_1^L \tau_{it} + \alpha_2^L r_i \tau_{it} + \alpha_3^L \tau_{it}^2 + \alpha_4^L r_i \tau_{it}^2 + X_{it}^L \beta^L + \gamma_t^L + \varepsilon_{it}^L, \tag{3}$$

where t represents calendar time and τ_{it} indicates tenure in the corporation for employee i at time t. Again, r_i is an indicator for whether worker i was referred by a current employee of the corporation, X_{it}^L is a vector of controls including entering staff level indicators and indicators for entering company division, shift, work schedule and leave status, γ_t^L is a calendar year fixed effect and ε_{it}^L is an idiosyncratic error. This log earnings regression is estimated using pooled data on employee half years, and allows us both to compare starting salaries for the referred and non-referred and to follow the effect of referral on employees' salary trajectories over time.

The estimated coefficient on referral in the log salary regression, reported in Table 7, indicates a 2.1 percent starting salary premium for referred workers. The coefficient is significant at the one percent level. The magnitudes of the referral coefficient estimates in the linear and log salary regressions are roughly consistent, given mean and median salaries of \$102,740 and \$97,377, respectively. Of course, there is wide dispersion in employee salaries in this corporation. Hence it is useful to consider the initial referral premium in both level and percentage terms, and the combination of the linear and the conventional log salary estimates allows us to do so. In sum, we find that an employee referral is associated with a starting salary premium of 2.1 percent, or more than \$1,300. This result bears out the predictions of not only Dustmann et al., but also Simon and Warner and Galenianos.[23]

[23] Simon and Warner also show evidence of higher initial wages when recollected jobs were based on referrals in their retrospective 1972 survey of scientists and engineers.

5.3 Prediction 3: The referred worker salary advantage diminishes over time

As discussed in Section 3.3, however, current theory of labor market referrals predicts that the referral effect will dissipate over time, and the salaries of referred and non-referred workers who remain with the corporation will converge. The log salary estimates reported in Table 7 provide a test of the referred salary premium's time trajectory.[24]

We find that the referral effect does indeed diminish over time. In all linear tenure specifications in Table 7, α_2, the coefficient on the interaction between the referral indicator and tenure in the organization, is negative and significant at the one percent level. In the quadratic specification with tenure squared, reported in column (3), the estimated values of α_2 and α_4 (i.e., the coefficients on the referral indicator multiplied by tenure and tenure squared) are both negative but the coefficients are not estimated very precisely.

Figure 1 depicts predicted salaries for referred and non-referred workers as tenure increases.[25] While the referred salary initially lies above the non-referred salary, referred and non-referred salaries are roughly equivalent after three years of tenure with the corporation. Indeed, 95 percent confidence intervals only rule out common referred and non-referred salary levels for the first two years of tenure in the corporation. This convergence of salaries after an initial advantage for the referred is consistent with the theoretical predictions of the Dustmann et al. and Simon and Warner models of labor market referrals.[26]

From five years of tenure on, the estimates predict a statistically significant salary advantage for the non-referred. It is not clear what to make of this eventual non-referred advantage in the context of the theory discussed earlier. Models like Dustmann et al. and Simon and Warner predict some convergence in referred and non-referred salaries, but do not include a source of advantage for non-referred workers who stay with the corporation. As we show in Section 5.4 below, we also find

[24] Estimates of a fixed effects specification of the above model, intended to account for unobserved heterogeneity in worker productivity and other characteristics, are available from the authors. Findings for the referred and non-referred salary trajectories are qualitatively similar to the estimates reported in Table 7.

[25] Note this figure is based on specification (3) in Table 7.

[26] It is important to note here that the model discussed in Section 3.2 and subsequent sub-Sections incorporates the effect of differential separations for referred and non-referred workers on salary gaps over time. Therefore, in the empirical exercise we do not need to correct our salary trajectory estimates for differential attrition, as the model's prediction is predicated on differential turnover. We discuss this issue further in Section 5.4. Importantly, and consistent with the theory, when we control for differential separation among referred and non-referred, any salary differences disappear: see Figure A1 in the Appendix, which plots salary slopes for employees who stay at the corporation at least five years.

that referred employees experience significantly lower turnover than non-referred. Taken together, these findings suggest a role for differential investments in firm-specific human capital, or perhaps for non-pecuniary gains related to differential affinity between employees already at the firm and referred vs. non-referred hires. A valuable innovation in the theory of labor market referrals, then, might be an extension of existing models that accounted for these observed patterns.

Finally, it is also evident in Figure 1 that all employees of the corporation enjoy a steep salary increase with tenure, which appears to be the dominant feature of salary trajectories in this corporation for both worker categories.

Returning to the simpler specification in Table 6, the remaining columns report results for identical specification

$$S_{i\tau} = \alpha^s r_i + X^s_{i\tau}\beta^s + \gamma^s_t + \varepsilon^s_{i\tau},$$

with the exception that τ (again) represents the years of tenure in the corporation at the date of observation. In other words, Table 6 shows results of the linear regression of salary level at tenure τ (in thousands of 2010 dollars) on referral status and worker characteristics at tenure τ. Again we see that the positive effect of referral on salary dissipates quickly. In the earlier years of tenure in the corporation, the referral coefficient tends to be positive, though statistically insignificant. After year four, the referral coefficient becomes negative and is statistically significant at six, eight and nine or more years of tenure in the corporation. Salary disadvantages for the referred are, on average, \$3,634, \$7,689 and \$13,343 at six, eight and nine or more years, respectively.[27]

In sum, referred workers in this corporation do in fact experience an initial salary advantage followed by a decline to non-referred salary levels, confirming predictions of theoretical referral models such as Simon and Warner and Dustmann et al. However, we also find a significant and economically substantial salary advantage for non-referred workers after five years. This is not consistent with the predictions of Simon and Warner, it does not appear to be consistent with the predictions of Dustmann et al (although it is not ruled out in their setup), and in general it is not clear how an eventual advantage for non-referred workers who remain with the organization might be aligned with existing theory.

[27] Simon and Warner also find that scientists and engineers recollect lower salary growth in their ongoing jobs when they were referred, based on their 1972 survey data. They do not attempt to determine whether the lower salary growth leads non-referred workers' salaries to overtake referred workers' salaries at any point.

5.4 Prediction 4: Turnover is lower for referred workers

Next we turn to the theoretical prediction, reviewed in Section 3.4, that referred workers experience lower rates of turnover after joining a firm. We model separation from the corporation using the discrete time proportional hazard framework found in Prentice-Gloeckler (1978) and Meyer (1990). The instantaneous separation hazard at tenure τ is

$$\lambda_{i\tau}^{D} = \lambda_{0}^{D}(\tau)\exp(Z_{i\tau}^{D}\delta^{D}), \tag{4}$$

where $\lambda_{0}^{D}(\tau)$ is a baseline match dissolution hazard that is permitted to vary with tenure in the corporation and

$$Z_{i\tau}^{D}\delta^{D} = \delta_{0}^{D}r_{i} + \delta_{1}^{D}\tau + \delta_{2}^{D}r_{i}\tau + \widetilde{Z}_{i\tau}^{D}\beta^{D}.$$

Here $\widetilde{Z}_{i\tau}^{D}$ includes entering salary, company division and staff level, current shift, leave status, part time status, and in some specifications some subset of the interactions of starting staff level and the referral indicator, an indicator for recession/post-recession dates and the interaction of the post-recession indicator with the referral indicator. We are primarily interested in the effect of referral on the separation hazard, and any variation in the referral effect on separation as tenure increases.

Table 8 reports estimates of hazard model (4). We specify the tenure dependence of baseline hazard $\lambda_{0}^{D}(\tau)$ in one of two ways. In columns (1) and (3) through (8), we impose a linear tenure dependence. Column (2) includes separate dummies for each observed six month interval with the corporation. Comparing the estimates in columns (1) and (2), it appears that allowing a very flexible tenure dependence in the baseline hazard has little effect on the estimates. Further, we have estimated specifications in columns (3) through (8) with both linear and fully nonparametric assumptions on the baseline hazard, and our qualitative results are essentially unchanged. In the interest of simplicity, we report column (3) through (8) estimates assuming a linear baseline hazard.

In addition, the estimated values reported in Table 8 are in terms of $\exp(\delta)$, for ease of interpretation. Where the regressor is an indicator variable, given (4), the reported $\exp(\delta)$ value can be interpreted as the proportional change in the hazard associated with moving from a regressor value of zero to a regressor value of one. This is measured relative to a baseline hazard, which represents the separation hazard of a full time, day shift, not on leave, mid-level, non-referred employee who

has just entered the corporation during the pre-recession period. For example, the $\exp(\delta)$ value in specification (1) associated with an on leave worker indicates that, perhaps not surprisingly, a worker currently on leave faces roughly three times the separation hazard of an employee who is not currently on leave, all else equal.

Table 8 estimates indicate that referred workers do indeed experience lower separation rates from the corporation. Specifications (1) and (2) show that referred workers are about 85 percent as likely to leave the corporation as non-referred workers, and these findings are significant at the ten percent level in each case.[28]

We find that most of this referral effect arises from the pre-recession period. Turning to specification (7), we see that pre-recession referred workers are 76 percent as likely to leave the organization as pre-recession non-referred workers, and this effect has a p-value of 0.045. However, the referral effect on separations for those hired after the start of the recession is much more moderate. For people hired after 2007, referred workers are only 96 percent as likely to leave the corporation compared to non-referred people, and this difference is not statistically significant. Similarly, if one estimates using only the pre-recession sample, as in specification (5), one finds that referred workers are 77 percent as likely to leave the corporation as non-referred workers, and the p-value for this estimate is 0.056. The period beginning with the recession was one of meaningful changes in employment practices for this particular corporation, as for many others. We find substantially decreased turnover from the start of the recession, and decidedly different hiring practices. Thus it is not surprising that employee referrals appear to function differently for this corporation from the start of the recession.

One might be concerned, given the predicted and observed tenure differential between referred and non-referred workers, that estimates of the salary dynamics of retained workers would reflect confounding dynamic selection effects. It may be helpful to note at this point that the goal of the salary trajectory estimates in Section 5.3 is to test the equilibrium predictions of models like Dustmann et al. and Simon and Warner. Their salary trajectory predictions pertain explicitly to the subset of referred and non-referred workers in ongoing matches, whose empirical analog is the set of referred and non-referred employees who are retained by the corporation. Hence our

[28] Simon and Warner find that scientists and engineers in their 1972 retrospective survey recall longer job duration when they were referred, all else equal. Datcher (1983) also finds lower turnover in referred jobs, using PSID data.

estimates of the salary trajectories of retained employees are, arguably, the appropriate objects with which to test these predictions.

5.5 Prediction 5: The referred turnover advantage also diminishes over time

The significant negative association between employee referrals and separation from the corporation does not appear to diminish with tenure, despite the predictions of the theory. The general findings regarding the relationship between tenure and separation in Table 8 appear to be that longer-tenured workers are significantly less likely to leave the corporation from the start of the recession on, but that tenure in the corporation bears no significant relationship to departure preceding the recession. Specification (3) adds a referral indicator times tenure regressor to the estimation, and based on the specification (3) estimates we see that the separation hazard increment associated with referral does not appear to change in any noticeable way with tenure. Despite the (reasonably intuitive) theoretical prediction that the lower departure rates for referred workers diminish over time as the surviving non-referred workers become a more selected and better-matched group, the empirical results indicate that, for this corporation at least, the decreased separation rate associated with employee referrals is relatively long-lasting.

5.6 Prediction 6: Referred workers have higher expected productivity

Theoretical predictions regarding referrals generally emphasize higher initial employer approximations of worker productivity for workers hired through referrals than for workers not hired through referrals. Though both worker productivity and employers' inferences regarding workers' productivity are difficult to measure, an employer's promotion decisions may offer a source of information on perceived worker effectiveness.

We model the promotion process using approximately the same approach we applied to the tenure process in Section 5.4. In the discrete time proportional hazard framework we apply, the instantaneous promotion hazard is assumed to be

$$\lambda_{i\tau}^{P} = \lambda_{0}^{P}(\tau)\exp(Z_{i\tau}^{P}\delta^{P}), \tag{5}$$

where $\lambda_{0}^{P}(\tau)$ is a baseline promotion hazard that we again allow to vary either linearly or completely

non-parametrically with tenure in the organization. This time

$$Z_{i\tau}^{P}\delta^{P} = \delta_{0}^{P} r_{i} + \delta_{1}^{P}\tau + \delta_{2}^{P} r_{i}\tau + \widetilde{Z}_{i\tau}^{P}\beta^{P},$$

with $\widetilde{Z}_{i\tau}^{P}$ including entering salary, company division and staff level, current shift, leave status and part time status, and, in some specifications, some subset of the interactions of starting staff level and the referral indicator, an indicator for recession/post-recession dates and the interaction of the recession/post-recession indicator with the referral indicator. Unlike separations as measured in our data, promotions may arrive more than once for some employees. Our model admits repeated failures, and second and later promotions do contribute to the reported coefficient estimates. We are primarily interested in the effect of referral on the promotion hazard, and any variation in the referral effect on promotion as tenure increases.

Table 9 reports the promotion model estimates. Looking first at our baseline specification in column (1), we find that referred employees are 93 percent as likely to be promoted over a given interval as non-referred employees, all else equal. This difference is not statistically significant at standard significance levels. So, despite the predictions of higher initial perceived productivity that arise from the theory, we cannot reject the hypothesis of equal promotion rates for the referred and non-referred, and, if anything, referred employees achieve promotion slightly more slowly than their non-referred peers.

Instead, other employee characteristics appear to drive promotion. Employees with longer tenure in the corporation are significantly more likely to be promoted. One year of tenure increases the promotion probability over the next six months by five percentage points, all else equal. Employees with higher starting salaries, conditioning on staff level, are more likely to be promoted. Not surprisingly, full time, day shift, and active status workers are more likely to be promoted. The relationship between staff level and promotion rate is non-monotonic. Support staff are promoted at only 52 percent the rate of mid-level staff, and this difference has a p-value of 0.003. Junior and executive staff are promoted at insignificantly higher rates than mid-level staff. However, senior staff are promoted at only 84 percent of the rate of mid-level staff, and this difference is significant at the ten percent level. Finally, the rate of promotions at this corporation increased following the start of the recession.

As in the case of separation, specification (2) indicates that the promotion results described in this section are robust to linear and non-parametric specifications of the tenure dependence of the hazard. Turning to specification (3), we find no significant difference in the tenure dependence of promotion rates between the referred and non-referred. Theoretical predictions regarding whether the initial higher productivity of referred workers would be sustained are unclear. In any case, the data for this corporation do not support a meaningful difference in employers' promotion decisions for referred and non-referred workers over time.

Of course, the extent to which the promotion results provide a test of the theoretical predictions regarding perceived worker productivity depend critically on the extent to which promotion decisions are a valid measure of perceived worker productivity. To the extent that promotions are a valid perceived productivity measure, our results do not support the claim that referred workers' perceived initial productivity is significantly higher than non-referred workers' perceived initial productivity.

5.7 Prediction 7: The variances of referred and non-referred workers' wages converge over time

Table 10 reports the comparison of the variances of initial salaries for referred and non-referred workers. We find that, for all workers in our sample, the variance of initial salaries for non-referred employees is 1.2 times the variance of initial salaries for referred workers, and this ratio differs from one at the one percent level. Hence initial salaries are more dispersed for non-referred workers. In the context of the theory in Section 3, the variance-lowering noisiness of the external market signal is not great enough to overwhelm the variance-raising effect of the external market reservation wage. As shown in Table 10, this pattern also holds for two out of four of the largest divisions in the corporation, as well as among shorter- and longer-tenured workers.

Figure 2 shows the trajectories of referred and non-referred salary variances from the hire date through 7 years of tenure, along with 95 percent confidence bands around the variance trajectories. We find that the referred salary variance lies below the non-referred salary variance, with non-overlapping confidence bands, for each of the first five years. This finding aligns with the predictions of Datcher (1983). At six years the referred variance rises toward the non-referred variance, and their confidence intervals intersect. By seven years the salary variances of referred and non-referred

workers are approximately identical. Thus the data for this firm are consistent with the model prediction that salary variances for referred and external market workers converge over time. Note that this type of wage variance convergence is peculiar to the learning model of referrals of Simon and Warner and of Dustmann et al., along with the "job shopping" model of Datcher. It is difficult to imagine a model of referred worker ability advantage that generates similar wage variance convergence.

5.8 Referral effects by skill level

There is strong empirical evidence that informal search methods are used more by workers with lower socioeconomic status and lower education levels, and for 'lower-status' jobs.[29] However, there is very limited work on the effect of referrals on outcomes by skill or education level. Using an indirect approach, Topa (2001) studies the magnitude of referral effects across neighboring census tracts in Chicago. He finds that the estimated spillover effects are stronger in tracts with lower education levels and with higher fractions of minorities. Using a different identification strategy to identify neighborhood effects in labor market outcomes, Bayer et al. (2008) find that the estimated referral effects are stronger for less educated workers, younger workers, and Asian or Hispanic workers.

The range of staff levels available in these data, and associated range of starting education and experience levels, in combination with sample sizes of 62,127 applicants, 1,774 workers and 12,447 worker-half years, allows us to make some inferences regarding differences in the role of employee referrals across the markets for different employee skill levels. In the interest of studying the role of referrals in lower and higher skilled labor markets, we introduce staff level-referral interactions in the hiring, salary, promotion, and turnover models above. The advantage of the present study relative to prior analysis of referrals by skill market is that it uses direct information on referrals together with detailed measures of job outcomes.

Looking first at the hires data, Table 11 reports estimates of expression (2) in which we have added either education requirement and referral interactions, in columns (1)-(3), or staff level

[29] Corcoran et al. (1980), Datcher (1983), Marx and Leicht (1992), all report higher usage for less educated job seekers. Elliot (1999) finds that informal contacts are more frequently used in high-poverty neighborhoods than in low-poverty ones. Rees and Schultz (1970) and Corcoran et al. (1980) both find that informal search methods are used more often for blue-collar than for white-collar occupations.

and referral interactions, in columns (4)-(6). Again, outcomes are an indicator for whether the applicant interviewed in columns (1) and (4), an indicator for whether the applicant received an offer in columns (2) and (5) and an indicator for whether the applicant received an offer restricting the sample to interviewees in columns (3) and (6). Our first observation is that referrals have a significantly greater impact on the overall probability of offer receipt for positions with lower education requirements. Applicants to postings requiring high school diplomas, associate's degrees and other educational credentials show significantly larger referral effects on offer probability than applicants to postings requiring college and graduate degrees. The additional effect of referral for high school, associate's degree and other requirement postings relative to college postings is 2, 4 and 3 percentage points, respectively, and each estimate is significant at the five or the one percent level. The high school and other education requirement effects appear to operate mainly through the effect of the referral on being interviewed, while the associate's degree effect operates primarily between the interview and the offer stage.

At the same time, referrals have a significantly larger positive impact on the probability of being interviewed for positions with a graduate rather than college degree requirement. Thus, referral effects seem to have a U-shaped relationship with skill level. We conjecture that the corporation may rely on referrals for different reasons at different points of the skill distribution. For positions with lower education requirements, the corporation may use referrals to detect worker traits such as reliability, punctuality, etc. At the high end of the skill distribution, the corporation may be looking for things like initiative, leadership, and strategic thinking. This would certainly be an interesting area for future research.

Turning to the staff levels, referrals have a similar relationship to offer receipt for support, junior and senior staff as for mid-level staff. Point estimates for support, junior and senior staff indicate a one percentage point smaller referral effect than for mid-level staff, and are in some cases significant.[30] For executives, however, the referral effect on offer receipt is 4.5 percentage points higher than the referral effect on offer receipt for mid-level staff, and this difference is significant at the one percent level. Estimated increments to the referral effect for executives relative to mid-level staff are large at both the interview and offer stages. Thus the estimates suggest that referrals play

[30] The point estimates also indicate a large negative effect of referral at the interview to offer stage for support staff, but, given the small and insignificant difference in the overall referral effect on offers for support and mid-level staff, it is not clear how much to make of this result.

a substantially different role in the hiring of executives than in the hiring of rank-and-file staff, and are again consistent with the idea that the corporation may use referrals to detect qualities such as leadership or strategic thinking.

In the employee log earnings regressions reported in Table 7, analysis of referral effects by staff level also reveals a non-monotonic pattern. Support staff experience a particularly strong salary referral advantage relative to mid-level staff. Junior staff and executives show significantly lower initial salary referral advantages than the reference category. The estimated referral advantage of 3.4 percent of initial salary is offset for junior staff by a significant 2.5 percent, indicating that junior staff have a net referral advantage of only about 0.9 percent of initial salary. More strikingly, the coefficient on the referral-executive interaction is -7.9 percent of starting salary, and is significant at the one percent level. On net, the referral effect on initial salary for executives is -4.5 percent relative to non-referred executives, and it is significantly different from zero. Hence for executives there seems to be a negative effect of referrals on initial salary. While the estimate for junior staff is not far out of line with the referral effects for the other staff levels, the estimates indicate decisively that referrals play a different role in determining executive salaries.

Returning to the separation results in Table 8, we find that the negative separation effect of referral we observe for the full sample appears to be largest among the support staff. The Table 8 column (4) point estimates for the referral and the referral times the support staff indicator interaction together indicate that referred support staff are *eight percent* as likely to leave the corporation as non-referred mid-level staff, and this estimated difference is significant at the five percent level. Further, the association between referral and the probability of separation increases roughly monotonically in staff level, going from a large negative association at the support staff level to a large positive association for executives. While support staff are much less likely to separate from the corporation if referred, referred junior, mid-level and senior staff are only somewhat less likely to separate if referred, with separation rates relative to non-referred mid-level staff of 87 to 88 percent. Echoing the results for initial salary, executives also demonstrate a unique referral-tenure relationship. We find that referred executives are substantially more likely to leave the corporation than non-referred mid-level staff. Based on the point estimates, referred executives are more than twice as likely to leave as non-referred mid-level staff. However, as a result of the relatively small sample of referred executives, this difference is not quite significant at conventional levels. Overall,

the separation results indicate large differences in the role of employee referral in labor markets for different skill levels, with a large positive association between referral and tenure in lower-skilled jobs and some evidence of a negative association between referral and tenure in higher-skilled jobs.

Moving to the promotion results in Table 9, we observe no significant differences between referred and non-referred promotion rates by staff level. In general, promotion practices appear to be quite similar for the referred and the non-referred.

In sum, employee referrals are associated with strong positive tenure effects for lower skilled workers. For most rank-and-file workers they also tend to be associated with higher starting salaries. However, referrals appear to function quite differently in the market for executives. Their referrals are associated with, if anything, *shorter*-lived matches and lower starting salaries. Our estimates clearly indicate different roles for referrals across markets for different worker skill levels.[31]

Finally, we have also run our empirical analysis separately for some of the largest divisions within the company, to see whether our results are robust to possibly different management practices within the company. Our findings are qualitatively very similar across the four largest divisions of the corporation, with some variation in the size of the estimated referral effects on outcomes. For instance, the estimated initial salary advantage for referred vs. non-referred workers ranges between 0.8 and 5.4 percent of initial salary across divisions. There is also some evidence in one division that referrals are associated to a higher promotion hazard, suggesting higher perceived productivity for referred hires. Overall, the results are remarkably similar across the entire corporation.

5.9 Referral match analysis

In this Section we investigate whether different degrees of similarity between referral provider and receiver are associated with different referral effects, in terms of the various theoretical predictions we have studied. We first look at salary levels and trajectories, and then consider separation and promotion hazards.

Table 12 reports the results of our log salary regressions, augmented by a set of dummy variables that describe the nature of the match between referral provider and receiver. Column (1) is a copy of Table 7 column (3); column (2) replicates column (1) with the (smaller) sample for which we have

[31] One caveat is that, as noted above, we have relatively few observations for executives in our sample. Further, some of our results – for instance on the negative association between referrals and job tenure for executives – seem to be driven mostly by the post-recession period.

referral match information; column (3) adds the referral match variables. We find that employees who received the referral from an older provider, someone in a higher staff level, someone in the same division, or someone who has been at the organization for less than two years have higher initial salaries than their counterparts. The magnitude of the effects ranges from an additional 1.8 percent salary advantage for referred workers when the referrer is in the same division, to a 4.8 percent additional salary advantage when the referrer is in a higher staff level.[32]

The age, staff level and division results seem very intuitive, as one would expect that older employees, those in higher positions in the organization, and those in the same division as the referral receiver may have a better understanding of the sort of skills that are required to succeed in the organization. At the same time, it is also possible that these sorts of providers can exert more influence and secure a higher initial salary for the referred worker. The result for tenure is also interesting: it may indicate that workers who have been relatively less time at the corporation have better informal contacts with the outside labor market and are better able to provide referrals for workers who are good matches for the organization.

These results, however, are based on *mean* salary differences. We are also interested in seeing how these different provider-receiver matches affect the salary slope of referred employees over time. Therefore we also run our log salary regressions interacting the referral match dummies with tenure and tenure squared at the organization. In Figure 3 we report salary slopes for different types of matches.[33]

Our findings are quite interesting. For those who are referred by someone in a different division, with less tenure at the organization, or in a higher staff level, the salary advantage relative to a non-referred employee seems to persist much longer than average: the difference is statistically significant up to seven years after being hired, whereas when we do not differentiate by the characteristics of the referral match the referral salary effect tends to dissipate after about three years at the company. In particular, the referral effect is initially stronger if the provider is in same rather than different division (consistent with our earlier result), but it reverses after three years. The referral effect is also stronger for providers with less tenure (vs. more) or in a higher staff level (vs. same

[32] These results are qualitatively consistent with those in Datcher (2006). She looks at the wage effects of referrals for different types of referral providers, and finds that older workers (who typically have higher incomes) tend to provide referrals for jobs associated with higher wages.

[33] We only report results for which there is a statistically significant difference between various referral matches. The full set of regression results and the tests of statistical significance are available from the authors upon request.

or lower), especially if the provider is two or more salary levels higher. The finding that after a few years those who were referred by someone in a different division tend to enjoy a significant salary advantage relative to the non-referred is particularly important to distinguish between the learning story explored here as opposed to a mere influence story. If the initial referral providers work in a different division of the organization, it is less likely that they are able to exert direct influence over the employee's salary progression during her stay at the company. Thus this is perhaps our cleanest piece of evidence in favor of the learning interpretation of referrals.[34]

Figure 3 also shows that if employees are referred by someone a decade or more older, or of the same race/ethnicity, then the initial referral advantage gets absorbed more quickly, within four to five years. Consistent with our previous finding, the referral effect is stronger if the provider is older (than same age or younger) and if the provider is of the same rather than different race or ethnicity. The same ethnicity result could be tied to the fact that social networks tend to be very assortative in the U.S. along racial and ethnic lines, so a signal about prospective match quality may be more informative for this type of referral matches, leading to a higher initial reservation wage and to a higher salary progression over time.[35]

Tables 13-15 report the impact of referral matches on promotion and separation hazards. In particular, Table 13 reports our baseline hazard models when we include all referral match dummies jointly. The only match characteristics that have a significant impact on the likelihood of a promotion are age, race/ethnicity and staff level. We do not find any significant effect of referral match differences on separations. Consistent with our salary regressions, those who received a referral from an employee of the same race/ethnicity are more likely to get promoted than a non-referred worker, and those who received the referral from someone in a lower staff level are much less likely to get promoted.

Tables 14 and 15 focus on age and staff level respectively: here we run the hazard model regressions only including match dummies for these characteristics one at a time. This allows us to compare the effect of a particular referral match to both non-referrals and other types of

[34] Datcher (1983) also finds evidence consistent with a learning model, and inconsistent with a "clout" theory of referrals, in which the referrer "can facilitate promotion, earnings opportunities, and receiving nonpecuniary benefits".

[35] Marsden (1987), (1988) using General Social Survey data shows that social networks of Americans exhibit a high degree of homophily (or assortative matching) with respect to race and ethnicity: individuals are much more likely to interact with members of the same racial or ethnic group than with other racial/ethnic groups (relative to random matching).

referral matches. We find that referred workers with older providers are associated with a lower chance of promotion both relative to non-referrals and relative to employees who received referrals from same-decade or younger providers. Therefore, while receiving referrals from older providers is associated with an initial salary advantage, it is also associated with a lower chance of promotion over time. Thus, this particular type of referral matches does not seem to denote the hiring of more productive workers for the organization.

On the other hand, when the referral comes from someone in a higher staff level, it is associated with a significantly higher likelihood of promotion, with respect to both non-referrals and providers in strictly lower staff levels. This effect is convex: those with referral providers who are two or more staff levels higher are even more likely to get promoted than those with providers in the same level or just one level higher. Therefore, this particular type of referral match (from a higher to a lower staff level) is associated with both steeper salary growth over time and faster promotions. Again, this finding is consistent with these referral recipients being more productive (or better matches for the organization), but we cannot exclude an influence interpretation of the referral.[36]

We have also explored whether referral providers are systematically different from other employees who do not provide referrals for new hires (see Tables A3 and A4 in the Appendix). We find that those employees who provide a referral, all else equal, tend to be less senior in the organization, with less tenure, and with a higher salary than non-referrers at the time of the referral provision. They are also more likely to be promoted. Thus, referrals seem to originate from relatively better-than-average employees in the organization, who may have relatively better connections with the external labor market (having joined the firm more recently). These findings seem more consistent with referrals being used to reduce uncertainty about prospective hires rather than as a way to exert patronage.

Interestingly, even *after* the referral provision, referrers continue to be more likely to be promoted and to experience higher salaries (controlling for other observed attributes), continue to be less likely to be in higher staff levels within the organization, and tend to have longer tenure at the corporation. The latter finding may signal that those who provide referrals are generally more satisfied at the workplace (enough to be willing to recommend the company to others) and therefore

[36] Referrals from higher staff levels are as likely to come from providers in different divisions as referrals from same or lower staff levels, so we cannot use this additional source of variation to further distinguish these possibilities.

tend to stay longer with the organization.

6 Conclusion

Our unique firm-level data on job candidate referral and subsequent careers in the firm allows us to address a series of open questions in the literature on job market referrals. We find that, in one sizable, diverse U.S. corporation, referred candidates are more likely to be hired, and hired referred workers enjoy a wage advantage for their first three years on the job, but after five years' tenure they experience a wage disadvantage. They stay with the firm longer, and their salary variance converges to that of non-referred workers over time. Each of these results is consistent with the predictions of established labor market referral models, particularly those that view the distinction between referred and non-referred workers from the perspective of Jovanovic-style learning about match productivity.[37]

Results that go beyond the confines of standard labor market referral theory include several findings on the role of referrals at different levels of skill and experience. Overall, referrals appear to play substantially different roles in the hiring of support staff and executives. Their relationship with the probability of a job offer follows something of a U-shape, with sizable, significant positive associations between referral and offer probability for both lower skilled and executive positions. Most rank-and-file workers experience substantial referral salary advantages, with the largest estimated advantage going to support staff. Executives actually experience a substantial starting salary disadvantage with referral. Finally, the association between referral and tenure in the firm is large and positive for support staff, and it decreases more or less monotonically with staff level. Executives are significantly more likely to leave the firm if they are referred.

Our analysis of the different types of referral matches (between referrer and referred) yields some additional insights. First, we find that most referrals take place between a provider and a recipient with similar characteristics in terms of age, gender, race/ethnicity, education, and who work in the same division or staff level. This is consistent, on the one hand, with the extent of assortative matching in social networks, and on the other hand with the idea that referrals tend

[37] More difficult to reconcile with existing theory are our findings that referred workers are typically not promoted any more quickly than non-referred workers, and that the (predicted) referral tenure advantage fails to decline over time.

to be used by the firm when they can provide a better signal about the referred worker's match productivity (assuming that higher affinity is associated with more informative signals). Second, we find some indication that referred workers may be more productive that non-referred, for some types of referral match: referrals from a higher to a lower staff level are associated with faster promotions; further, the salary trajectory of referred workers stays persistently higher than that of non-referred when referral providers are in a higher staff level, have relatively low tenure, or work in a different division. The tenure and division findings in particular are difficult to reconcile with a "favoritism" or "influence" interpretation of referrals.

One would like to make some inference regarding whether referrals are good for firms and workers. Though we believe that our data offer a considerably more complete picture of the behavior of referrals than was previously available, at least for one sizable and diverse U.S. corporation, we do not have access to exogenous variation in workers' referral status. (It is difficult to imagine a source of such variation in standard labor market contexts.) As a result, we cannot make causative claims about the impact of job referrals. What we have done so far is to test the equilibrium predictions of leading models of labor market referrals, as well as to enrich economists' descriptive understanding of the behavior of referrals by provider-recipient relationship and across skill levels. Our results, by and large, support the predictions of learning-based models of labor market referrals. Such models, for example Dustmann et al. and Simon and Warner, predict that referred candidates are hired in equilibrium only where such hires increase total surplus to the firm and worker. While we cannot claim to have demonstrated, in a direct sense, a positive effect of referral on wages or firm profits, we can say that our results support a family of models that predict worker-firm surplus gains from the use of referrals.

Our findings suggest a few interesting avenues for further research. First, we find that on average referred workers tend to stay longer with the company, but eventually experience slower salary growth than non-referred ones. This seems puzzling. As we discussed above, one possible explanation is that referred workers may invest relatively more in firm-specific human capital, which would limit their outside options over time and therefore reduce their bargaining power within the corporation. Another possibility is that the eventual salary disadvantage is compensated by non-pecuniary aspects of the job match, such as a more enjoyable work environment because the referred worker has social contacts within the corporation. We plan to explore this possibility in future work

by constructing measures of affinity between the referred worker's attributes and those of his or her proximate co-workers.

Second, we find some evidence of a U-shaped relationship between education or skill level, and the size of the referral effect on hiring outcomes. We conjecture that this non-monotonic relationship may be explained by different roles played by referrals at different points in the skill distribution. At low education or skill levels, referrals may be used to better detect desirable worker traits such as punctuality and reliability, whereas at the higher end of the distribution they may be used to screen for traits such as leadership and strategic vision. This could be another interesting area for future research, both theoretical and empirical.

A Additional Results

The Table 5 estimates of the probabilities of being interviewed and receiving an offer provide some ancillary information on the corporation's hiring process, which we present here. Unsurprisingly, a larger number of applicants significantly increases the competitiveness of the position. However, the magnitude of this effect is small: 100 more applicants for a position are associated with a 0.1 percentage point decrease in the probability that an applicant is interviewed. Surprisingly, the proportion of applicants that are referred increases the likelihood that an applicant for the position receives either an interview or an offer, and this effect is significant. A 10 percentage point increase in the proportion referred is associated with a 0.88 percentage point increase in the probability of an interview, and a 0.44 percentage point increase in the probability of an offer.

Staff level coefficient estimates indicate that support staff positions are significantly less competitive than mid-level staff positions, but that junior, senior and executive level staff positions are comparably competitive to mid-level staff positions. Similarly, positions that require a high school diploma are significantly less competitive than positions that require a college degree, particularly at the interview stage, while associate's degree, college degree and other education requirement positions are similarly competitive. However, we do find that positions that require a graduate degree are significantly more competitive than positions that require a college degree, particularly at the interview stage.

Screening from the application to interview stage becomes stronger over time in our data, with the probability of being interviewed conditional on applying decreasing by 0.5 percentage points per year. Yet the probability of receiving an offer conditional on having been interviewed increases significantly over time, and the overall offer probability for applicants does not vary significantly over time. Finally, we see a lower probability for the applicant of being interviewed following the start of the recession, with, again, no significant change in the overall probability of an offer. Together these estimates suggest that screening resources are being shifted to earlier points in the hiring process over the course of the panel.

Notes: Some referrals were dropped from this sample because their referrer information was missing. In the case where someone is referred by two people of different genders, we count the referrer that is the same gender. Similarly, when someone is referred by two people, we count the referrer with the same ethnicity, the oldest age, the highest salary grade, and the most education. Only 10 referees are referred by two people in our sample.
